Abstract

A cross sectional study was done in three purposively selected districts of horse-breeding districts in the Arsi-Bale highlands of Ethiopia, namely Assassa, Adaba and Dodola from March 2015 to June 2015. The present study was aimed at investigating the effect of natural infection by Trypanosoma equiperdum (dourine) in horses, determining the pathological lesions on the nervous system; and to reveal the presence of the parasite in the nervous tissue or cerebrospinal fluid or in both. For this purpose, we used two horses having clinically positive and strong seropositive result in Card Agglutination Test for Trypanosomosis (CATT) test and were subjected for post mortem examination and followed by histopathological test. Pathological lesions in the nervous system of infected animals included degenerative changes and neuronal necrosis, which were more pronounced in the lumbar and sacral parts of spinal cord than cervical and thoracic parts and brain tissues, and cellular infiltration and degeneration in the left sciatic nerve than the right sciatic nerve. The pathological lesions were associated with absence of the parasite (in Giemsa stain) and viral infection (in cell culture) related to increased immunological reactions in the lumbar and sacral parts of spinal cord and sciatic nerve as well as increase in numbers, size and activity of the phagocytic cells in these regions.

Keywords: Arsi-Bale highlands; Dourine; Ethiopia; Histopathology; Horse

Introduction

In Ethiopia there are two regions (South West and North West) with high prevalence of Trypanosomosis. In addition, six species of the disease recorded, from which T. congolense, T. vivax and T. brucei are the important species causing major economic loss in domestic animals. The other species of major economic importance are Trypanosoma equiperdum which affect horses and Trypanosoma evansi affecting camel [1].

Trypanosoma equiperdum is known to cause Dourine, which is with characteristics of genital edema, incoordination, ocular lesions, anemia, progressive emaciation, fever, cutaneous eruptions and facial paralysis [2]. Equines are the only natural host of T. equiperdum [3]. Horses are highly susceptible to T. equiperdum and they die after lasting 1-2 years with chronic disease. Donkeys and mules, even if are susceptible to the infection, they may remain asymptomatic or show mild syndrome [4].

The main lesions of the disease appear in genital organs because of the transmission through the act of coition. It is known that trypanosomes cannot be found either in the peripheral or central nervous system, therefore the effect on nervous system is can be caused by toxins released by the organism. Detail diagnosis to demonstrate the parasite, biochemical, serological and molecular tests should be used in addition to the use of clinical signs [5].There are few studies conducted in Ethiopia with regard to Dourine like based on clinical signs [6], serologically by ELISA and CFT [1], by ELISA, CATT/ T. evansi and Latex/ T. evansi [7] and molecular by PCR [8]. Therefore the objectives of the present study was to describe the neurologic signs and the pathologic findings in the nervous system of horses naturally affected by dourine; and to reveal the presence of the parasite in the nervous tissue or cerebrospinal fluid or in both.
Materials and Methods

Study Area

The study was conducted in three districts of the Arsi-Bale highlands of Ethiopia, namely Assassa, Adaba and Dodola. The Arsi-Bale highlands are found in the Oromiya Regional State with the altitude of 500 to 4,130 meters above sea level and a bimodal rainfall occurring from July to October and April to May. Average annual temperature of 20-25°C and rainfall of 200 mm in the lowlands as well as 10-15°C and a rainfall of 400 mm in the highlands are recorded [9].

Study Population and Design

The study animals include sexually mature horses suspected with T. equiperdum infection under natural condition. The study was cross sectional (observational) study. A total of 20 local breed of horses, which were kept under traditional management system of free grazing and clinically positive for dourine, were considered as study animals and out of them two highly seropositive mares purchased for detail and thorough post mortem examination and histopathology. Castrated animals and animals with trypanocidal treatment recently were excluded purposively from the sample.

Clinical Examination

Clinical examination done by observation based on symptoms and signs mentioned by Claes et al. [10] as pathognomonic sign like typical cutaneous plaques, with sizes ranging from extremely small to hand sized. In addition the characteristics of the disease such as damage to the genitalia, edema and tumefaction were used as a diagnosis tool [3]. The last stage of dourine is characterized by progressive anemia, disorders of the nervous system mainly paralysis of the hind legs and paraplegia and, finally, death. The clinical examination was done on affected horses that were coming to the clinics of the three selected horse-breeding districts of the Arsi-Bale Highlands. Based on the clinical signs, horses that showed the neurologic signs with hind leg paralysis and pathognomonic signs in the genitalia were selected for further diagnosis and histopathology.

Parasitological Tests

The parasitological test was done as described in Woo [11], Reid et al. [12]. From 12 horses suspected clinically, about 7.5 ml of blood samples were collected from jugular vein using venoject needles and heparinized vacutainer tubes. The blood collection site was wiped with cotton wool soaked in alcohol. Capillary tube were filled up to three fourth volumes and centrifuged for 5 minutes in micro-centrifuges at 12,500 rpm, for parasitological test. Then, the capillary tubes were placed in a holder known as viewing chamber and microscopically examined at 10X magnification to look parasites on the buffy coat. The tests were conducted at field level in Arsi-Bale highlands in Assassa, Dodola and Adaba veterinary clinic.

Serological Test

Whole blood samples collected for serological testing were allowed to clot over night at room temperature. Separated serum was filled in to serum cryogenic vials and stored at -20°C until testing. CATT for Trypanosoma evansi, which is a rapid direct agglutination test, that uses formaldehyde fixed, Coomassie stained, freeze-dried trypanosomes of T. evansi VAT RoTat 1.2 was employed to demonstrate the presence of antibodies in serum samples according to Claes et al. [12]. The tests were conducted at Dodola veterinary clinics. Positive results were determined at cut-off point dilutions 1:4 [13].

Post Mortem Examination

Out of twelve horses thoroughly examined, two mares suffering from classical nervous signs and having strong positive for CATT were euthanized with sodium pentobarbital at 100 mg/kg dose through intravenous injection for postmortem and Histopathological examination. The CSF (cerebrospinal fluid) was collected from the atlanto-occipital space as described by Furr and Andrew and stored at -20 °C until processing. Samples of CSF were centrifuged at 3,000 rpm for 15 min, where trypanosomes are detected at the bottom layer [14].

Thick smears were prepared and stained with Giemsa solution for morphological examination under oil immersion. Gross lesions in the different parts of the nervous system were recorded. Histopathological samples were taken at thickness of 5-10mm from brain (cerebral cortex and cerebellum), spinal cord (cervical, thoracic, lumbar and sacral parts), and peripheral nerve (sciatic nerves). Tissue samples were fixed with buffered formalin, and transported to National Animal Health Diagnostic and Investigation Center (NAHDIC), for histopathology.

Histopathological Examination

Formalin fixed nerve tissues were trimmed at appropriate thickness. Tissues were dehydrated using ascending concentration of alcohols, cleansed by xylene and impregnated with molten paraffin wax. Following embedding with paraffin, tissues were sectioned at 5-μm thickness [15] and, stained with hematoxylin and eosin stains. Duplicate sections were stained with Giemsa for parasitological examination for the detection of the parasite in the nerve tissues. Slides were then examined under microscope.
Detection of Viral Growth in Cell Cultures

This has been performed to exclude viral diseases having similar neurological clinical signs such as equine infectious anemia and equine herpes virus 1 infection. A total of four spinal cord and sciatic nerve samples were collected from two mares and preserved in Phosphate Buffered Saline (PBS) solution containing gelatin and antimicrobial agents and kept in refrigerator (4°C) until and during transport in ice box to National Animal Health Diagnostic and Investigation Center (NAHDIC), for viral growth detection in cell culture.

Viral culturing techniques: Tissue samples were homogenized using mortar and pestle, centrifuged at 3400 rpm for 10 min and 0.5 ml of the supernatant was inoculated on the confluent BHK-21 cells and incubated at 37°C. Viral growth was recognized by the Cyto Pathic Effect (CPE), characterized by change in shape, cell detachment, fusion leading to syncytium formation, the presence of inclusion bodies and cell death [16].

Ethical Clearance

The study animals, horses, especially the two mares are euthanized based on the permission obtained from the Animal Research Ethical Review Committee, that provided the author an ethical clearance certificate with Ref. No. VM/ERC/004/03/07/2015, and date of review: VM/ERC/004/07/015, 17/04/2015.

Results

Parasitological and Clinical Observations

A total of 20 naturally infected mares were studied. No rise in body temperature was observed in any of the infected animals. Based on the characteristic dourine signs, clinically sick horses were observed (Figure 1). In 4 mare animals, external genitalia edema, mucopurulent vaginal discharge with foul odor and depigmented scars over the external genitalia were the prominent signs observed in the genital form of the disease (Figure 1B and C).

Serological and Histopathological Examination

Out of the 12 sera tested with CATT, 2 mares showed high positivity while 8 mares showed moderate seropositivity. Mares with high seropositive result were purchased for post mortem examination. There were no remarkable gross lesions in the brain, spinal cord and sciatic nerves in both mares slaughtered. No trypanosomes were detected in all Giemsa Stained Smears (CSF).
and tissue sections; and in blood samples under haematocrit centrifugation technique “WOO’s technique”. Nervous tissue using haematoxylin-eosin stained tissue sections for histopathological examinations showed microscopic lesions primarily on the sacral and lumbar regions the left sciatic nerve and of the spinal cord. The primary lesions were degenerative changes (central chromatolysis) (figures 2, 3, 4, and 5) and neuronal necrosis (figure 2 and 4) of the spinal cord, and cellular infiltration and Wallerian degeneration of the sciatic nerve (figure 6).

Figure 2: Lumbar region of spinal cord, Horse No. 2. Central chromatolysis (open arrows); shrunken, necrotic neuron (closed arrows). H&E stain 10x.

Figure 3: Lumbar region of spinal cord, Horse No. 1. Central chromatolysis (open arrow); Perineuronal satellite oligodendroglia (closed arrows) surround a degenerate neuron with condensed chromatin and little cytoplasm. H&E stain 40x.

Figure 4: Sacral region of spinal cord, Horse No. 2. Central chromatolysis (open arrows); shrunken, necrotic neuron (closed arrows). H&E stain 40x.

Figure 5: Sacral region of spinal cord, Horse No. 1. Central chromatolysis (open arrow); Perineuronal satellite oligodendroglia (closed arrows) surround a degenerate neuron with condensed chromatin and little cytoplasm; white arrow (Astrocytes) have larger nuclei (condensed chromatin) and the cell membrane and cytoplasm are rarely seen in no diseased conditions. Microglial cells with small, dense elongated nuclei (inside star). H&E stain 40x.
**Detection of Viral Growth**

Viral tissues were cultured in the monolayer of BHK-21 cell line to detect the presence of viral growth; however, no Cyto Pathogenic Effects (CPE) was observed.

**Discussion**

Data collected in this study demonstrate that most of the signs observed coincide with those reported in previous studies. The clinical picture of the disease corresponds closely to that described in earlier reports [3, 17-19].

Weight loss was observed in all animals, especially in 12 of the mares selected. There was no any appetite loss. It should be underlined that weight loss is one of the early signs that could lead the veterinarian or owner to suspect Dourine. No rise in body temperature was observed in any of the infected animals, which is in agreement with other studies [20] but it is often reported in the literature [3, 21].

Ventral edema were not seen in all observed mares and this may be attributed to the stage of the disease as most of them were in the third stage, but genital edemas were observed in few of animals. This could be explained because the horses were from natural infection and already showed signs of active disease on arrival at the veterinary clinic. Caporale [22] suggested that the first stage of the disease was not reported or undetected at the holding. In addition, the route used for experimental infection was not the natural route of infection which is sexual transmission. Oedema of the mammary glands was not seen in all mares in the present study; however, Vulpiani et al. [23] reported its persistence until the animal was euthanized when present. The classic “silver dollar” plaque was not seen in the present study. According to Barrowman [24], these lesions are rarely occur in the infected in nature. These lesions are also difficult to differentiate from wheals triggered by other causes (allergic reactions to blood transfusion or insect bites) [23], but they are considered pathognomonic by some authors [3; 21], although their presence seems to be inconstant.

Most authors report only the sporadic presence of this sign [3,18,19], although it has been reported more frequently in outbreaks in Europe and North Africa [20]. Some attribute this difference to the T. equiperdum strain involved and others to the immune response. In any case, presence of wheals should lead to suspicion of Dourine infection [23]. Thus, although the plaque lesion may be pathognomonic, its rare occurrence, transient nature and possible confusion with other skin eruptions limit its diagnostic value.

Woo test showed no parasite in the blood samples taken from long-standing cases of unknown duration. This is supported by Barrowman [24], in his report stated that an attempts to demonstrate the parasite in the blood of long-standing cases of unknown duration were unsuccessful; however, it has been possible to demonstrate the more prolonged presence of the trypanosomes in circulating plasma in horses whose actual infectious service date was known. Except Rouget [25] and Gari et al. [26] who reported the parasite in blood from horses suspected of dourine, most authors have experienced difficulty in demonstrating the parasite in naturally infected horses [17,19, 27] and have had only occasional success at the onset of the disease. Parkin [28] recorded the more consistent finding of the parasite during the disease early stages in horses infected by blood at sub-inoculation. In the present study, despite the absence of the parasite in the blood by parasitological (Woo test) test, out of 12 horses examined by serological test (CATT test) two mares’ revealed strong seropositive results, but there was no any gross pathological lesions observed on the different part of spinal cord, brain and on the sciatic nerves.

There are very limited information on the pathology of dourine either experimental or natural infection in horses, especially on the nervous system of horses. In the current study the presence of neurological signs confirms the tropism of T. equiperdum for the peripheral nervous system and the lack of involvement of the central nervous system, in contrast with other groups of trypanozoan [24,29]. In contrast with T. equiperdum, McCully and Neitz [30] reported that the most remarkable lesion in horses experimentally infected with T. brucei were found in the brain, and consisted of a diffuse meningoencephalitis characterized by massive perivascular cuffs of large lymphocytes, plasma cells, and a few typical cells of Mott. In the current study, degenerative changes and neuronal necrosis were present in spinal cord, and cellular infiltration and degeneration in the sciatic nerves. As a result, from both slaughtered mares, the microscopic lesions of the nervous system were found to involve primarily the lumbar and sacral regions of the spinal cord and the left sciatic nerve. Histo pathological changes in these tissues have been recorded by Barrowman [24] who reported radiculitis and polyneuritis, involving cellular infiltration and degenerative changes of the spinal nerves and spinal ganglia, extending along the larger sciatic nerves as the primary lesions. In contrast to the involvement of the central nervous system in T. gambiense infections in man [31] and experimentally prolonged T. brucei infections in horses [30], histopathological changes have not been reported in the central nervous system of under natural T. equiperdum infections, except that Matt 1906, 1907 found the lesion in the spinal nerves extending into the posterior columns of the spinal cord [17]. According to Rodrigues et. al. [32], T. evansi infection of horses, unlike to T. equiperdum, the pathological le-
sions involving the brain and characterized by moderate to severe perivascular lymphoplasmacytic meningoencephalitis, necrosis, edema and hemorrhage. In this study an attempt has been made to demonstrate whether the parasite present in the cerebrospinal fluid or in the nervous tissue, or in both samples, but the trypanosome was not seen in either of the samples. This is contrary to Barrowman [24], who reported that trypanosomes were shown to be present in the CSF of horses dying from the nervous form of the disease and in live, naturally-infected horses with nervous manifestations, whereas they were not found in CSF from horses without these signs.

No growth of virus was seen in the present study complementing that the slaughtered mares were not infected with viruses, which potentially confuse with the disease and thus helps the author to exclude viral disease having similar neurological signs with dourine such as equine infectious anemia and equine herpes virus 1 infection.

**Conclusion**

Dourine is endemic in the study area in Arsi-Bale highlands, Oromia region, Ethiopia. The current study revealed that even though the parasite is not found in the CSF and nervous tissues, it causes degenerative changes and neuronal necrosis in the affected parts of spinal cord, cellular infiltration and degeneration of sciatic nerve. In nutshell, the disease revealed moderate degree of microscopic pathological lesions on the nervous tissues at the third stages of the disease.

**Acknowledgment**

The authors would like to thank the VLIR-UOS Ethio-Belgium team project for providing research facilities like CATT test and postmortem kits, and also financial support for the accomplishment of this research work.
