Abstract

Liver fibrosis is the final common stage of the most chronic liver diseases; it is caused by several factors which lead to a major worldwide health care burden. Over the decades, the understanding of the liver fibrosis disease was growing rapidly, several studies reported that this progress could be regressed or reversed, which give us a bright prospect in developing anti-fibrotic therapies.

In this experiment, liver fibrosis was fully developed after CCl₄ induction for 7 weeks in eight animals. Clinical pathologic parameters, four indicators of hepatic fibrosis in monkey showed similarly changes in human. All animals had liver fibrosis after 1.5 months of CCl₄ induction, and liver fibrosis still existed after 9 months’ recovery periods, the fibrosis stages in most animals had no obvious regression without treatment. Bio mathematical analysis of the liver fibrosis would aid to utilize the anti-fibrotic therapies and their derivatives for various biomedical applications.

Keywords: Animal Model; CCl₄; Liver Fibrosis

Introduction

Liver fibrosis is defined as an abnormal response of the liver to persistent injury, characterized by the excessive accumulation of collagenous extracellular matrices (ECMs), and therefore involves both wound healing and fibrotic processes [1-3]. The repair processes occur right after liver injury, which can take either of two distinct paths: one way called regenerative path in which injured cells are replaced by the same type of cells; the other is connective tissue replaces normal parenchymal tissue in an uncontrolled fashion, which is known as fibroplasias or fibrosis [4-8]. Persisting injury caused uncontrolled repair processes, lead to the damaged tissues/organs undergo substitution by over-abundant ECM and suffer from extensive, pathological fibrosis [3]. The onset of liver fibrosis is usually insidious, advanced liver fibrosis results in liver failure and portal hypertension and is associated with an increased risk of liver cancer [9]. Severe end-stage liver disease (cirrhosis or hepatocellular carcinoma) is associated with morbidity and mortality, and orthotopic liver transplantation is often indicated as the only effective therapy [10]. However, liver transplantation has several disadvantages, shortages of organ donors, the commitment of recipients to lifelong toxic immunosuppression, and recrudescence of the original disease in transplant recipients, therefore effective antifibrotic treatments are urgent unmet medical needs [11, 12].

Liver fibrosis research can be assigned to two broad groups: in vitro model including cell culture model [13,14], human tissue culture [15], and in vivo experimental animal models. Cell behaviour and the effect of specific mediator could be studied in in vitro model, but it clearly cannot recapitulate the event that occur in vivo. As we all know, liver fibrosis is developing disease with potentially dynamic processes that resulted from the complexed interplay of resident and incoming cells in a microenvironment. Animal models have been used for several decades to study fibrogenesis and to validate anti-fibrotic effects of potential therapeutic approaches [16,17]. Animal models allow for (i) comprehensive study of questions that may not be able to address in human studies, (ii) multiple sampling at strategic times during the development vs. resolution phases, (iii) experimental testing with restriction of the minimal number of variables [18].
Current animal model in liver fibrosis research are allocated in four main categories, the first category is via the cholestatic mechanism that damage the biliary epithelium including surgical bile duct ligation model [19], gene knockout or transgenic model [20,21], dietary models by feeding with 3,5-Diethoxy carbonyl-1,4dihydrocollidine (DDC) or α-Naphthylisothiocyanate (ANIT) [22,23]. The second category is induced by hepatotoxins such as CCl₄ [24], Thio Acetamide (TAA) [25], or Dimethyl Nitrosamine (DMN) [26], that belong into toxin-induced liver models. The third category is activated by metabolic liver injuries including both alcohol induced fibrosis and NASH-associated fibrosis [27-30]. The fourth category is induced by autoimmune responses via injecting heterologous serum to elicit liver fibrosis [31]. Most of these models were established in rodent animals. Although rodent models can mimic the liver fibrosis development to some extent, several differences between murine and human need to take into consideration; such as the different number and proportion of distinct immune cell populations in the liver and the different marker molecules to identify corresponding immune cell subsets [32], and diversity in RNA expression is reflecting the fundamental physiological differences between mice and humans [33]. Studies revealed that the subsets of circulating classical and non-classical monocytes show very different ratios in humans (90%:10%) and mice (50%:50%) [34]. Nonhuman primates are essential and irreplaceable animal models in human disease research because genetic, anatomical and physiological similarity to humans.

High-fat diet and/or CCl₄ induced rodent liver fibrosis was widely investigated [24, 35], but few studies report monkey liver fibrosis. Alcohol induced liver fibrosis model were developed in rhesus monkeys, which take 3 years [36]. Another study combined CCl₄ subcutaneous dosing with chronically fed high-fat diet and alcohol in drinking water for 16 weeks to establish liver fibrosis model in cynomolgus monkeys [37]. Both studies used alcohol as a major inducer. In order to establish a non-alcoholic liver fibrosis monkey model with a single stimulus within a reasonable time frame and to selectively target the liver, we chose to deliver CCl₄ through the portal vein.

**Material and Method**

**Animal and Husbandry**

Cynomolgus monkeys (3-6 years, 3-7 kg) were provided by Hainan Jingang Biotech Co., Ltd. All animals were single-housed in stainless steel cages equipped with a bar type floor and an automatic watering valve, these cages conform to standards set forth by the US Animal Welfare Act. The rooms controlled humidity at 40% to 70%, temperature at 18°C to 29°C, 10 to 20 air changes/hour and 12-hour light/dark. Regular or high fat diet and fresh fruit were fed daily. Protocols for all the animal studies were approved by the Institutional Animal Care and Use Committee (IACUC) (WuXi AppTec Co., Ltd, Suzhou, Jiangsu province, The People’s Republic of China).

**Reagent and Food**

**Experiment**

Animals had portal vein cannulation surgery. Briefly, animals were anesthetized through trachea intubation with isoflurane during surgery, the animals lied on its back and general sterilized in operation area, exposed portal vein and selected a branch of mesenteric vein at the far end. PE catheter was cannulated into the portal vein. After securing the catheter, the other end of catheter was connected with a heparin cap to confirm the catheter unobstructed. The heparin cap was placed in muscle layer subcutaneously. After a 20-28 days’ recovery period, the animals were ready to use.

Eight convalescent portal vein cannulated animals were assigned into this experiment. Animals were dosed with CCl₄ formulated in PEG 400 (400 mL/L) via intravenous bolus injection into portal vein. Animals were received escalating dosage at 0.1 mL/kg once weekly, 0.1 mL/kg twice weekly and 0.15 mL/kg twice weekly (Figure 1), all animals were put into recovery phase after the last dose.

![Dose schedule of CCl₄ during model induction phase.](image)

**Figure 1:** Dose schedule of CCl₄ during model induction phase.

Blood samples were collected before and weeks 1, 2, 4, 6, 8, 12, 24, 46 after first dosing, all blood samples were collected from a peripheral vessel into commercially available tubes containing Potassium (K⁺) EDTA or plain with separating gel before CCl₄ dosing on the specified day. Serum samples were stored at -60 degree or lower until analysis.

Liver biopsy and ultrasound B examination were conducted in this experiment. Animals were anesthetized with ketamine hydrochloride (10 mg/kg), lied on his back, sterilized appropriately, used ultrasound B (Vet-M7, Mindray) to keep away from big vessel and gall bladder, and then inserted auto biopsy gun (accut 14G x 115mm, TSK, Japan) to collect liver tissue. After the procedure, animals were observed daily by experienced technician till its recovery.
Sample Analysis

Whole blood samples (anti-coagulation EDTA$\text{K}_2$) for haematological parameters were analysed by an automatic analyzer (ADVIA 2120, Siemens). Serum samples for clinical chemistry parameters were detected by an automatic analyzer (HITACHI 7180, Hitachi High-Tech Science Systems Corporation). Serum samples for four indicators of hepatic fibrosis Laminin (LN), Hyaluronic Acid (HA), Collagen Type IV (CIV), and N-Terminal Propeptide of Collagen III (PIIINP) parameters were determined through Radio Immunoassay (RIA) method in ADC CLIA 400 automatic plate immunoassay analyzer (Autobio).

Pathological Examinations

Liver tissue or biopsy samples were fixed in 10% formaldehyde, trimmed, processed, embedded in paraffin, sectioned, stained with haematoxylin and eosin and Sirius red staining, and then examined microscopically. Liver fibrosis is classified by using Metavir system [38]: No fibrosis (F0), Fibrous portal expansion (F1), Few bridges or septa (F2), Numerous bridges or septa (F3) and Cirrhosis (F4).

Results

Monkeys were dosed for up to 7 weeks, total CCl$_4$ dose volume were from 1.43 to 3.46 ml. All animals entered into recovery phase after last dosing. The mean animal body weight (4.61±0.56 kg) decreased about 9% (4.20±0.48 kg) on week 7, but increased to 4.82±0.42g and 5.45±0.52 kg at 6 and 12 months respectively (Figure 2).

Liver enzymes Aspartic Transaminase (AST), Alanine Aminotransferase (ALT), Alkaline Phosphatase (ALP), Gamma-glutamyl Transpeptidase (GGT) concentration were increased significantly after CCl$_4$ induction, the mean peak levels were 77.6±9.37 U/L, 1071±146 U/L, 1482±453 U/L and 151±29.3 U/L respectively. (Figure 3). Total Bilirubin (TBIL) level was increased and reached to peak (8.4±1.64 µmol/L) at week 4. The total protein (TP), albumin (ALB) and albumin/globulin (A/G) ratio were declined 11% (70.2±1.98 g/L), 25% (31.2±1.26 g/L) and 41% (0.69±0.11) after dosing of CCl$_4$ (Figure 4). All changed values returned gradually to normal in recovery period. Other clinical chemistry parameters do not change significantly. Whole haematology parameters including red blood cell, white blood cell, haemoglobin and other related items were in normal range during this experiment (data not show).
Figure 3: Sequential changes of liver enzymes in the process of liver fibrosis (n=8). Values are expressed as the mean ± SEM.

Figure 4: Sequential changes of other clinical pathologic parameters in the process of liver fibrosis (n=8). Values are expressed as the mean ± SEM.

The HA, LN, and PIIIP parameters were increased from 72.8±21.6 ng/mL to 136±32.0 ng/mL, 201±16.9 ng/mL to 299±28.8 ng/mL, 26.1±5.27 ng/mL to 49.5±5.94 ng/mL after CCl₄ induction respectively. HA and LN level restored to normal after a recovery period, but the PIIIP value was still higher at week 24 than baseline (Figure 5). The mean CIV value was 34 ng/mL in week 4, beside that all the other CIV values were below the limit of quantitation (15 ng/mL).
Figure 5: Indicators of hepatic fibrosis curve in cynomolgus monkeys pre and post CCl₄ induction (n=8). Values are expressed as the mean ±SEM.

Pathology examination in liver biopsy samples showed that fibrosis was found for all animals (Figure 6). Liver fibrosis were existed persistently during the recovery period (Table 2), it did not cure naturally without treatment. Irregular or nodular surface and blunt edges in liver were observed under ultrasound B examination (Figure 7).

Figure 6: Pathological changes in liver tissue (200 X). The pictures Sirius red staining (A) and HE staining (D) are presented F3, which the formed numerous bridges or septa, small number of pigmented macrophages (hemosiderin) and mononuclear inflammatory cells were observed. The pictures (B, E) are presented F2, few bridges or septa with inflammatory cells. And the pictures (C, F) are normal liver.

Table 2: Liver fibrosis stages for individual animal at different months after initial CCl₄ dosing.
GGT levels and TBIL indicate liver toxicity. The increasing of four liver enzymes AST, ALT, ALP, and GLB indicate liver damage. ALT is predominantly found in the liver, with clinically negligible quantities found in the kidneys, heart, and skeletal muscle. In contrast, AST is found in the liver, heart (cardiac muscle), skeletal muscle, kidneys, brain, and red blood cells. Therefore, ALT is a more specific indicator of liver damage than AST. The increasing of four liver enzymes AST, ALT, ALP, and GLB levels and TBIL indicate liver toxicity.

ALB and TP, and A/G ratio were decreased. ALB is produced in the liver, impaired liver cannot synthesized effectively and maintain ALB level. Whereas, globulins are produced in the liver or immune system. This might be the reason why GLB is not changed during CCL₄ induction. The ratio of AST/ALT > 1 (AAR) has been proposed as a test of cirrhosis in human [43], while other study demonstrate that AST/ALT ratio is confounded when used in alcoholic and many other acute and chronic fatty infiltrating liver diseases [44], and not recommended for evaluation the stage of fibrosis. Among the monkeys were diagnosed as liver fibrosis, the AST/ALT ratios were below 1.0 throughout the study.

The process of liver fibrosis is characterized mainly by cellular activation of hepatic stellate cells (HSCs) and are able to express and deposit large quantities of extracellular matrix components [45, 46]. Liver ECM components include collagen type I, III, and IV, fibronectin, undulin, elastin, laminin, hyaluronan, and proteoglycans were higher than normal in advanced stage [47]. HA, LN, PIIINP were increased, those were consistent with previous studies [48-50]. But N-terminal pro-peptide of collagen type III (PIIINP) level also elevated in chronic pancreatitis [32] and HA levels may be elevated after meal or glucose drink [51], they are not specific for liver fibrosis.

The ideal biomarker should: 1) Specific for liver; 2) Readily available and standardized between all laboratories performing diagnostic biochemistry/haematology; 3) Not subject to false positive results, for example due to inflammation; 4) Identifies the stage of fibrosis [52]. Currently, no non-invasive markers are specific and capable of providing accurate information about fibrogenesis and the extent of fibrosis in the liver. The utility of serum models such as Fibrotest [53], Fibrometer [54], Fibrospect [55], Hepascore [56] were used to predict fibrogenesis, but currently cannot replace the gold-standard method liver biopsy [57].

Fibrosis stage is assessed by Metavir (stage 0–4) score. We can found that increased fibrillar eosinophilic material (H&E stained slides) and red Sirius Red stained were noted in the periportal (Centro acinar) area, this change generally limited to individual lobules, but also with extension from one portal tract to

Discussion

The kinetics of fibrosis development can be roughly divided into three phases: acute injury, initiation of fiber formation and advanced fibrosis [39]. CCl₄ is metabolized by hepatocytes, giving rise to toxic trichloromethyl (CCl₃) radicals by CYP2E1, an enzyme expressed in perivenular hepatocytes. It induces thus an acute Centro lobular necrosis which triggers a wound healing response: 1. recruitment of phagocytic and inflammatory cells to clear necrotic zones, 2. activation of fibrogenesis and increased ECM, 3. proliferation of parenchymal and non-parenchymal cells to replace dead cells; which would reconstitute liver integrity. When the insult is repeated, successive rounds of wound healing occur prior to resolution of the previous one resulting in fibrosis accumulation [21]. All animals developed liver fibrosis after CCl₄ administration via portal vein. Haemolysis could be induced rapidly when CCl₄ quickly injected into portal vein, and liver cell necrosis could reduce the liver’s ability to metabolize and excrete bilirubin leading to a build-up of unconjugated bilirubin in the blood.

Liver fibrosis evaluation methods can be divided into invasive and non-invasive [40]. Non-invasive method includes serum tests, RNA expression analysis and imaging techniques. These methods may be performed repeatedly, allowing for ongoing monitoring of potential fibrosis in vivo [41]. In this study, the mean ALT was increased almost 20-fold after administrating CCl₄. ALT was released from liver tissue into the circulation in proportion to the degree of hepatocellular damage. Its level is thought to be one of the most sensitive markers of liver injury and liver disease progression [42]. Mean AST level increased less than 3-fold after CCl₄ induction. ALT is predominantly found in the liver, with clinically negligible quantities found in the kidneys, heart, and skeletal muscle. In contrast, AST is found in the liver, heart (cardiac muscle), skeletal muscle, kidneys, brain, and red blood cells. Therefore, ALT is a more specific indicator of liver damage than AST. The increasing of four liver enzymes AST, ALT, ALP, GGT levels and TBIL indicate liver toxicity.

ALB and TP, and A/G ratio were decreased. ALB is produced in the liver, impaired liver cannot synthesized effectively and maintain ALB level. Whereas, globulins are produced in the liver or immune system. This might be the reason why GLB is not changed during CCL₄ induction. The ratio of AST/ALT > 1 (AAR) has been proposed as a test of cirrhosis in human [43], while other study demonstrate that AST/ALT ratio is confounded when used in alcoholic and many other acute and chronic fatty infiltrating liver diseases [44], and not recommended for evaluation the stage of fibrosis. Among the monkeys were diagnosed as liver fibrosis, the AST/ALT ratios were below 1.0 throughout the study.

The process of liver fibrosis is characterized mainly by cellular activation of hepatic stellate cells (HSCs) and are able to express and deposit large quantities of extracellular matrix components [45, 46]. Liver ECM components include collagen type I, III, and IV, fibronectin, undulin, elastin, laminin, hyaluronan, and proteoglycans were higher than normal in advanced stage [47]. HA, LN, PIIINP were increased, those were consistent with previous studies [48-50]. But N-terminal pro-peptide of collagen type III (PIIINP) level also elevated in chronic pancreatitis [32] and HA levels may be elevated after meal or glucose drink [51], they are not specific for liver fibrosis.

The ideal biomarker should: 1) Specific for liver; 2) Readily available and standardized between all laboratories performing diagnostic biochemistry/haematology; 3) Not subject to false positive results, for example due to inflammation; 4) Identifies the stage of fibrosis [52]. Currently, no non-invasive markers are specific and capable of providing accurate information about fibrogenesis and the extent of fibrosis in the liver. The utility of serum models such as Fibrotest [53], Fibrometer [54], Fibrospect [55], Hepascore [56] were used to predict fibrogenesis, but currently cannot replace the gold-standard method liver biopsy [57].

Fibrosis stage is assessed by Metavir (stage 0–4) score. We can found that increased fibrillar eosinophilic material (H&E stained slides) and red Sirius Red stained were noted in the periportal (Centro acinar) area, this change generally limited to individual lobules, but also with extension from one portal tract to
another (bridging fibrosis), in addition, small number of pigmented macrophages (hemosiderin) and mononuclear inflammatory cells were present.

However, there were some limitations when using liver biopsy evaluation. Firstly, hepatic fibrosis may not be homogenous throughout the liver, the size of biopsy specimen is not large enough to contain whole hepatic lobule, and it only represents a tiny fraction of organ. Sampling error (25%-40%) may result in poor reproducibility [58]. Secondly, it’s an invasive procedure that caused pain and major complication occurring in 40% and 0.5% of patients, respectively [59]. Thirdly, there is well known observer variability amongst pathologists in categorizing the degree of fibrosis, no matter how precisely defined the stage [60]. The liver fibrosis scores minor changed in different months in our experiment, it mainly depends on the liver biopsy sample size and sampling location, some histopathologic images including whole hepatic lobules which contribute to making judgement, and it’s really challenge to evaluate the fibrosis score in images with partial hepatic lobule. Increasing the biopsy sample numbers may decrease the erroneous judgement, but noting that biopsy is an invasive procedure.

Many imaging techniques have emerged for liver fibrosis detection and assessment, such as ultrasound [61], Computed Tomography (CT) [62] and Magnetic Resonance Imaging (MRI) [63]. The image of ultrasound B showed clearly changes during the induction in our study, but it only produces specific findings, with very limited sensitivity and cannot assess the fibrosis stage, especially in early and intermediate stages. CT and MRI have the same problem [64,65]. All in all, it would be better to combine both non-invasive and invasive method for comprehensive assessment of the liver stage.

Liver fibrosis reversal is still a debated topic. When administrating of neutralizing TIMP1-specificantibody decreases the collagen content in CCl4-induced fibrosis [53], and the reversibility of fibrosis was found in experimentally induced cholestasis in rat [56]. In humans, spontaneous resolution of liver fibrosis can occur after successful treatment of the underlying disease. Hepatitis C caused liver fibrosis could be reverse after treatment [54]. It may take years for significant regression to be achieved, the time course varies depending on the underlying cause of the liver disease and its severity. Some experimental evidence suggests cirrhosis might reach a point of no return. Using the CCl4-intoxicationrat model of liver fibrosis, the remodelling of advanced cirrhosis is limited and the liver remains cirrhotic even after a very protracted recovery period [55]. Our study indicates the same process after 9-monthrecovery period, liver fibrosis remains existing. In the other hand, it means a long term therapeutic window using this model.

Conclusion

Liver fibrosis represents a classical outcome of many chronic liver diseases. Animal models are being used for several decades to study fibro genesis and to evaluate the anti-fibrotic potential of therapies and strategies. Previous study demonstrated that monkeys and human have similar liver architecture including hepatocyte, portal regions, bile duct, portal vein and liver veins [66]. Our study showed that liver fibrosis could be established by only given CCl4, which testify the hypothesis. In current stage, many technologies could assist diagnose liver fibrosis, but no one indicator can diagnosis the diseases except for pathological result. The monkey model is a better system to explore the prevention and treatment of chronic liver diseases and develop new diagnostic techniques and novel treatment.

Conflict of Interest

We have no conflict of interests to disclose and the manuscript has been read and approved by all named authors.
