Abstract

Introduction: Cerebrospinal Fluid (CSF) leak is a common complication of surgery involving the lumbar spine. However, although there are various therapeutic options for CSF leak, there is currently no optimal technique, and the choice of therapy often depends on the surgeon’s cumulative experience. The aim of this study was to describe the successful treatment of CSF leakage using blood injection therapy along the drain removal tract.

Technical Note: We enrolled 7 consecutive patients who underwent lumbar surgery at our institute. The surgeries performed included decompression in two patients (one microendoscopic surgery), fusion in four, and an epidural cyst resection in one. After finding a CSF leak, we injected about 10 ml of blood from the patient into the drain tract. CSF leak did not recur after the blood injection in any of the seven patients. Following just one day of bed rest, the symptoms of intracranial hypotension disappeared with no instances of worsened symptoms of back pain, lower limb pain or fever.

Conclusion: We propose this route of blood injection therapy as a novel method for the treatment of CSF leak after lumbar surgery.

Keywords: Blood Injection; Complication; Cerebrospinal Fluid Leak; Lumbar Spine; Lumbar Surgery

Introduction

Cerebrospinal Fluid (CSF) leak is a common complication of lumbar spine surgery [1-3], causing persistent headaches, nausea, vomiting, walking difficulties, and carries a high risk of meningitis. However, although there are various therapeutic options for CSF leak, there is currently no optimal technique. The choice of which technique to perform in each case usually depends on the surgeon’s cumulative experience. The purpose of this study was to examine the clinical efficacy of a blood injection therapy for CSF leak following lumbar surgery.

Patients and Methods

We enrolled 7 consecutive patients undergoing lumbar spine surgery at our institution, none of whom suffered from diabetes (1 male, 6 females, mean age 67.4 [range, 49-82] years) (Table1).
The patients and/or their families provided informed consent that data from their case would be submitted for publication. The surgeries performed included decompression in two patients (one microendoscopic surgery), fusion in four, and an epidural cyst resection in one. In five cases, CSF leak from dural tears was noted. In four cases out of five, we sutured the dura and reinforced it using a small piece of polyglactin 910 (Vicryl Knitted Mesh, Ethicon, Somerville, New Jersey) and fibrin glue (Bolheal, Astellas, Tokyo, Japan) [4]. In microendoscopic decompression, we used a small piece of polyglactin 910 and fibrin glue without suturing the dura. After repairing the dural tear, we checked the CSF leak using the Valsalva maneuver. We also used soft fluted silicone drain (Blake drains, Ethicon, Somerville, N.J.) [5] in all surgeries (drain size: 19 French in 6 cases, 10 French in one case) and all were drained at the same pressure. In all cases, the patients’ lumbar dressings were saturated with clear fluid (Figure 1a) and they had intracranial hypotension syndrome, with symptoms such as postural headaches on moving from a lying to standing position. In addition, we measured the glucose concentration of the exudate using urine dip test paper. We diagnosed CSF leak when the glucose concentration was less than 100 mg/dl. After diagnosing a CSF leak, we performed venesection from the patient’s medial cubital vein. We removed the silicone drain and injected about 10 ml of blood into the drain tract with an indwelling needle (Figure 1b). The patient’s clinical status was assessed following the blood injection, and was based on the presence of the following: evidence of recurrence of CSF leak, intracranial hypotension symptoms, low back pain, lower limb symptoms, and fever.

LSS means lumbar spinal stenosis. Fr means French, MED means microendoscopic laminectomy

All patients were advised to have a day of bed rest, and reassuringly all patients could stand and walk the next morning. CSF leak did not recur after the procedure in any of the patients. The symptoms of intracranial hypotension resolved, and no complications such as worsening back pain, lower limb pain or fever occurred.

**Discussion**

Our current results demonstrate that this simple procedure for postoperative CSF leaks provides a good alternative to re-operation. All our patients were advised to have a day of bed rest following the blood patch injection and CSF leak did not recur in any of the patients. Several methods are used for the management of CSF leak including direct suturing [1,6], percutaneous injection [7,8], drainage therapy [9-11] and blood patch [9,12-14]. However, to our knowledge, there have not been the procedures like ours ever. One well-known and widely accepted management option is surgical repair either by meticulous direct primary closure of
the dura or augmented closure by means of fat, muscle tissue or a fascia graft. Although these seem to be the most reliable method for CSF leak, four cases in our study suffered CSF leak after surgical repair in which we sutured the injured dura and reinforced it using polyglactin 910 and fibrin glue. Patel, et al. [8] assessed the effectiveness of CT-guided percutaneous injection of fibrin glue made from patients’ blood into the epidural space in a case series of 23 CSF leaks. In 15 of 23 cases, the symptoms were absent or markedly decreased after the procedure and a period of overnight bed rest. However, the complication of aseptic meningitis occurred in 5 cases. In addition, it took several days to prepare the cryoprecipitate from patient’s blood. Epidural blood patch and drainage therapy were also reported as other alternative procedures to surgical closure.

Lauer, et al. [12] reported the effect of epidural blood patch for CSF leak after lumbar decompression surgery. The clinician passed a Tuohy needle beside the surgical incision and injected 20ml of patient’s blood to L4-5 epidural space. The next day, the patient noted complete resolution of headache and was able to stand without discomfort, however, three days after this procedure, dull back pain occurred, radiating to the left leg. The differences between our procedure and standard epidural blood patch therapy are shown in Figure 2, highlighting the fact that it can be difficult to find the epidural space immediately following lumbar surgeries using the standard epidural blood patch procedure. We suggest that by using our drainage tract method, these problems may be overcome.

Figure 2: Approaches to blood injection to seal a CSF leak. Left: The procedure used in this case series. Entering via the drain tract may be the most accurate way of reaching a dural tear, enabling us to seal both the leakage point itself and the route from dura to skin by using less than 10ml blood. Right: Using the standard epidural blood patch technique, about 20-30ml blood is required. In addition, the drain tract is not sealed up with blood.

Shapiro, et al. [11] reported that the success rate of lumbar subarachnoid catheterization and drainage for 107 CSF leak cases was 94%; however, complications can occur such as infections (5%), occlusion of the drain requiring replacement (9%); and transient nerve root irritation (14%). Jackson-Platt drainage also was used for 16 CSF leaks, though the drain remained in place for 10-14 days and 5 patients needed reoperations. These previously reported methods require a specialist technique, requiring recuperation for several days, and is not successful in all cases. In our opinion, our proposed method of injection of blood along the drain removal tract may be the most accurate way of reaching the dural tear, sealing both the leakage point itself and the route from dura to skin. A benefit of this procedure is that it can be repeated if the blood injection is unsuccessful on the first attempt. However, various limitations to our proposed approach should be recognized. Although this method may be a useful procedure for treating CSF leak, it must be acknowledged that this is an experimental procedure, a small sample size is reported here and side effects similar to those seen in epidural blood patch therapy could be expected. Also, although we performed MRI in a few cases at an early stage in the collection of this series to check the size of the dural tear and its site, tears could not be seen on imaging. We noted that there was no pseudomeningocele in these patients, suggesting that large dural tears would not have been present. As we have no post-repair imaging data, we do not know to what extent the blood injection sealed the dural tear. In future studies, therefore, imaging using injection of contrast medium into the drain tract may provide further information. Nevertheless, this is the first report to use the blood injection therapy along the drain removal tract for the treatment of CSF leak, and may provide an alternative to surgical closure. In conclusion, our method of blood injection along the drain removal tract was performed without difficulty in seven cases and, following just one day of bed rest, was effective with for all cases. We propose this route of blood injection therapy as a novel method for the treatment of CSF leak after lumbar surgery.
