**Abstract**

**Background:** Lipoma is the most frequent benign mesenchymal neoplasm’s that affect the human body. They are composed of mature adipocytes and are enveloped by a fibrous capsule. The oral vestibule and jugal mucosa are the most commonly affected intraoral sites, and the tumors are characterized by painless increase in size, soft consistency, yellowish color, sessile or pedunculated base, and slow growth rate.

**Objective:** To report a case of giant facial lipoma and to review the main diagnostic and therapeutic aspects of this pathology.

**Case report:** NRS, a 64-year-old female patient, presented with increasing facial volume for 7 years. Tumescence was observed from the genial to the mental regions, with intraoral and extra oral protuberance. Surgical removal was chosen as treatment.

**Final remarks:** The histopathological analysis confirmed the diagnosis of lipoma. In cases of large lesions, surgery remains as the mainstay of treatment.

**Abbreviations:**

CT : Computed Tomographic

NRS : Patient Name Abbreviation

**Keywords:** Lipoma; Oral Neoplasms; Oral Surgery

**Introduction**

Lipomas are benign neoplasm’s of mesenchymal origin [1] composed of mature adipocytes divided into lobules separated by fibrous septum and surrounded by a thin fibrous capsule [2,3]. They are the most frequent mesenchymal neoplasm’s that affect the human body, being commonly observed in the thorax and in extremities [1]; around 20% in the head and neck region; and only 4 to 5% in the oral cavity [4].

The intraoral sites affected by this tumor include the tongue, floor of the mouth, palate, oral vestibule, and jugal mucosa. The latter two sites are the most common, accounting for 50% of all intraoral cases [5,6]. The etiology of this tumor is uncertain, but endocrine disorders, infections, traumas, alcoholism, and inherited traits are believed to be predisposing factors [6]. This type of tumor is uncommon among children, and individuals older than 40 years tend to be more frequently affected at varying rates. There is no predilection for race and its distribution between genders seems to be balanced, with a slight predominance of male individuals, as pointed out by some studies [6,7]. When lipomas affect the oral cavity, they exhibit a painless increase in size, mobility, soft consistency, and a yellowish color [8]. Most tumors measure 10 to 19 mm; however, their size may be a lot bigger due to their progressive growth [9].
As lipomas are asymptomatic, they are neglected by patients, and many of them only seek medical care when the tumor has reached a large size and is compromising functional activities, such as chewing and speaking, or interfering with the placement of dental prostheses [10]. Given that lipomas do not resolve spontaneously and have a progressive growth, surgical intervention is usually recommended. Treatment of oral lipomas, including all histological types, consists of complete surgical excision. After this procedure, recurrence is rare [4]. The aim of this study is to review the clinical and therapeutic aspects of lipomas, especially those in the oral cavity, and to describe an uncommon clinical case of a 64-year-old patient with a giant facial lipoma.

**Case Report**

NRS, 64-year-old, diabetic and hypertensive female patient presented with increasing facial volume for about 7 years. She complained of sporadic pain and trauma to the region before the development of the tumor. On physical examination, there was a flaccid, mobile lesion measuring approximately 12 cm from the right genial region to the mention, circumscribed to the soft tissues, without hyperalgesia, with evident intraoral and extra oral involvement. Oral mucosal tissue looked normal (Figure 1 A-B). The ultrasound scan revealed a thicker hypoechoic region, not well circumscribed, with lipomatous appearance in subcutaneous planes and more superficial lesion in the anterior jugal mucosa (Figure 1C).

![Figure 1](image1.png)
**Figure 1(A-C):** A) Extra oral tumescence extending from the genial region to the mention. B) Intraoral image showing vestibular bulging. C) Ultrasound scans showing thicker hypoechoic layer, not well circumscribed, and lipomatous aspect in subcutaneous planes.

Surgical treatment was indicated and after preoperative tests, the lesion was rejected. After direct incision of the mucosa, a soft yellowish mass was observed. Because of evident surgical distinction between the lesion and the tissues, a blunt dissection was performed until complete excision of the lesion (Figure 2). No vital structures were directly affected, but the dissection eventually showed close contact between the lesion and the skin.

**Figure 2:** A) Incision in right oral mucosa for lesion exposure. B) Dissection and determination of lesion borders. C) Total excision of the tumor. D) Gross image of the surgically removed tissue.

Even though the gross aspect of the lesion was highly suggestive of lipoma, the specimen was sent for histopathological analysis, which did not detect malignancies and confirmed the diagnosis (Figure 3). The patient had an uneventful recovery and did not have any recurrence, as evidenced in her follow-up visit 2 years after the surgery (Figure 4).

**Figure 3:** A) Low-power photomicrograph showing fatty cells and connective tissues with capillary blood vessels. B) Histological examination showing mature adipocytes.
Imaging exams have an important diagnostic value. Computed Tomographic (CT) scans are useful in determining the accurate location of the lesion, and they usually reveal a hypodense mass circumscribed by a thin capsule that is not enhanced by contrasting agents [11,12]. CT and ultrasound scans were used as complementary exams in the present study. Magnetic resonance is also useful, as the margin of lipomas tends to be clearly visible in this kind of exam. The visualization of the capsule based on the black margin substantially aids in the final diagnosis. Such distinction cannot be made by CT scans [11,12,16].

Ultrasoundography can also be used. It is easy and quick to use, inexpensive, and provides good identification of superficial tissues, which are usually hypoechoic. However, this diagnostic modality has poor image resolution [16]. This type of lesion is treated preferably by surgical excision [17,18], but some authors have described satisfactory results with the use of electrocautery and laser for removal of intraoral lipomas [19]. Cases of recurrence are uncommon, but in case of intramuscular variants, there could be recurrence, and it is widely known that liposarcomas may develop after recurrent lipomas. Despite the low rates of recurrence after surgical excision, postoperative follow-up is important and the prognosis is good in most cases [18,19]. In the case reported herein, the lesion was totally removed, with no evidence of recurrence after 2 years.
